Abstract

Purpose: This study aimed to investigate the prevalence of complications in adjacent teeth and implants when the occlusal scheme changed from canine guidance to group function due to implant placement in canine sites and to compare them according to prosthesis type.

Materials and Methods: This study included 41 patients, in whom 52 implants were placed at canine sites by the same clinician. The biological and prosthetic complications of canine implants, adjacent teeth, and implants were recorded. Fractures or mobility due to the traumatic force of occlusion in adjacent teeth were also recorded. The implants were divided into three groups according to the prosthesis type: (1) single crown (SC); (2) fixed partial denture splinted with anterior implants (SA); and (3) fixed partial denture splinted with posterior implants (SP). The prevalence of complications was compared between the three groups using the chi-square test.

Results: Nine implants were restored with a single crown, 26 implants were splinted with anterior implants, and 17 were splinted with posterior implants. The prevalence of complications in canine implants was not significantly different between the three groups. Fracture of the adjacent teeth and biological complications of the adjacent implants occurred only in the SP group.

Conclusion: The results of this study suggest that changes in the occlusion scheme due to canine implants can affect adjacent teeth and implants. Canine implants splinted with posterior implants could be more harmful than single and canine implants splinted with anterior implants.

Ⅰ. Introduction

The lateral occlusion schemes include canine-guided occlusion, group function occlusion, and bilateral balanced occlusion.1 The concept of canine guidance is that only canine teeth contact the opposing teeth during lateral excursion,2 and this has been considered the optimal occlusion scheme.3 However, the biomechanical properties of dental implants
differ from those of natural teeth. Implants are anchored directly in the alveolar bone without the periodontal ligament (PDL). Therefore, the implants remain in their original position during chewing, while natural teeth are inserted into the PDL space, resulting in an over-occlusion state of the implant. In addition, proprioception is lower around the implants than natural teeth, meaning that excessive forces can be exerted on an implant during a lateral excursion. Therefore, when an implant replaces a canine tooth, the lateral excursion is often guided by group function rather than canine guidance. A canine implant does not contact the opposing teeth on the working side, and adjacent teeth are included in the lateral excursion.

Changes from canine guidance to group function in lateral occlusion schemes can result in lateral forces on adjacent teeth or implants that have not contacted opposing teeth during a lateral excursion, which can induce occlusal trauma in these teeth or implants. The effects of lateral occlusion schemes on teeth are controversial. Canine guidance was considered to protect other teeth by discluding them during lateral excursion and it has been shown that group function is related to progressive occlusal wear. In contrast, another study found that variations in lateral occlusion schemes do not affect the amount of tooth wear. However, the possibility of occlusal trauma remains. Clinical and radiographic indicators of occlusal trauma include fremitus, mobility, occlusal discrepancies, wear facets, tooth migration, fractured teeth, thermal sensitivity, discomfort or pain while chewing, widened PDL space, and root resorption and cemental tear.

Lo et al. confirmed that changes in lateral occlusion schemes result in variations in the strains of the peri-implant. In addition, occlusal overload was believed to be associated with porcelain fracture, fracture of components of implant-supported overdentures, and loosening or fracture of abutment screws. Occlusal overloading is also considered as one of the main causes of marginal bone and implant prostheses failure. In particular, the lateral loading on dental implants can induce high stresses in the crestal bone, resulting in a loss of osseointegration and excessive marginal bone loss.

This study aimed to investigate the prevalence of complications in adjacent teeth and implants when the occlusal scheme changed from canine guidance to group function due to implant placement in canine sites and to compare them according to prosthesis types, such as single implant restoration and implant-supported fixed partial denture.

II. Materials and Methods

This study retrospectively collected data from 52 implants placed at canine sites in 41 patients by the same clinician between November 2011 and December 2017. All patients underwent regular check-ups. All implants were restored using a group function scheme. Patients aged <19 years were excluded. The
sex and age of the patients were recorded and periodontal health was evaluated according to clinical attachment loss (CAL). The patients were assigned to four groups according to the mean CAL value (non-periodontitis, <1 mm; mild periodontitis, 1-2 mm; moderate periodontitis, 3-4 mm; and severe periodontitis, >5 mm). Data on the reason for extracting the canine, implant placement site, prosthetic type of opposing dentition, and implant prosthesis type were obtained.

Complications of canine and adjacent implants were recorded. Biological complications included gingival swelling, pain, suppuration, and marginal bone loss >2 mm. Prosthetic complications included cement loss, screw loosening, porcelain chipping, and porcelain fracture. Screw fractures and fixture fractures were not observed in any case during the 3−9-year follow-up period. Fractures or mobility due to the traumatic force of occlusion in adjacent teeth were also recorded.

Fig. 1. Panoramic radiographs of patients in (A) single crown (SC), (B) fixed partial denture splinted with anterior implants (SA), and (C) fixed partial denture splinted with posterior implants (SP). The asterisks indicate the canine implants evaluated in this study.
The implants were divided into three groups according to the prosthesis type: (1) single crown (SC); (2) fixed partial denture splinted with anterior implants (SA); and (3) fixed partial denture splinted with posterior implants (SP). Figure 1 shows panoramic radiographs of the patients in each group. The prevalence of each complication was evaluated according to the group and intergroup comparisons were performed using the chi-square test. All statistical analyses were performed with SPSS software (version 23, SPSS, IL, USA).

The study protocol was reviewed and approved by the institutional review board of the National Health Insurance Service Ilsan Hospital (IRB no. NHIMC 2019-04-010).

III. Results

Twenty female patients included in this study were treated with 26 implants, and 21 male patients were treated with 26 implants. The mean age of the patients was 57.2 years (range, 20−82 years). The reasons for the extraction of canines included congenitally missing teeth, dental caries, periodontitis, tooth fracture, and root rest. There were nine implants in the SC group, 26 in the SA group, and 17 in the SP group.

Data are N or N(%) values. The significance for age was evaluated using one-way analysis of variance (ANOVA) and those for others were evaluated using chi-square test. *p < .05
SP group. The patient- and implant-related variables of these groups are listed in Table 1. The mean age and severity of periodontitis differed significantly between the three groups ($p < .05$), as did the severity of periodontitis ($p < .05$).

The main reason for the extraction of canines was congenital missing in the SC group, periodontitis in the SA group, and dental caries in the SP group (Fig. 2). However, the difference was not significant between the three groups when evaluated using the chi-square test ($p > .05$).

The mean period from implant placement to the onset of complications was 26.7 months, ranging from 8.6 to 51.3 months. Complications were observed in 34.6% of canine implants (23.1% showed prosthetic complications and 11.5% biological complications). The prevalence of complications in adjacent teeth was 7.7% and that in adjacent implants was 34.6%.

Table 2 lists the complications of canine implants, adjacent teeth, and adjacent implants in the three study groups. The difference in the prevalence of complications from canine implants was not significant between the three groups ($p > .05$). However, prosthetic complications tended to have a higher prevalence in the SA and SP groups than in the SC group, while biological complications showed the opposite tendency. Complications of adjacent teeth occurred only in the SP group. Fracture of adjacent teeth showed significant intergroup differences in prevalence ($p < .05$). The success rate, the percentage of adjacent teeth that did not show complications, was significantly different between the three groups ($p < .05$). There were no complications from adjacent implants in the SC group because that group did not have adjacent implants. The SA group showed only prosthetic complications, while three adjacent implants in the SP group showed biological complications. The prevalence of biological complications showed significant differences between the SA and SP groups ($p < .05$), while the difference in the prevalence of prosthetic complications was not significant ($p > .05$).

IV. Discussion

When a dental implant replaces a lost canine, the lateral excursion is often guided by group function rather than canine guidance. Therefore, this study investigated the prevalence of complications in adjacent natural teeth and implants when the occlusal scheme changed from canine guidance to group function due to implant placement at canine sites.

The overall prevalence of complications from canine implants was 34.6%, comprising 23.1% of prosthetic complications and 11.5% of biological complications. The most common complications are screw loosening and loss of retention. These prevalence rates are similar to the reported prevalence rates for all implants. Considering the relationship between excessive overload and peri-implant bone loss, changes in the occlusal scheme from canine guidance to group function effectively reduced the excessive forces or lateral forces applied to canine implants in this study. The prevalence of complications from canine implants did not differ significantly between the three groups (p > .05).

Physiological function and patient acceptance are similar between the different lateral occlusion schemes, but teeth can be affected by the occlusion scheme. The effect of lateral occlusion scheme on the degree of tooth wear is controversial. However, teeth can experience traumatic occlusion or excessive occlusal forces due to changes in lateral occlusion schemes. Cervical abfraction is one of the clinical signs of excessive occlusal forces. However, in this study, a chart review did not report any
cases of cervical abfraction that require treatment; therefore, cervical abfraction was not considered a
diagnostic criterion.

The prevalence of tooth or implant complications adjacent to canine implants was 15.4% in this study.
However, it is difficult to conclude that these complications occurred because the implants were placed
in the canine and the canine guidance was avoided. Implant placement at any other site can result in
excessive occlusal force on adjacent teeth when the occlusion of implants is altered to prevent occlusal
overload of implants. Resen et al. showed implant-associated vertical root fractures in adjacent
endodontically treated teeth. They suggested that the increased occlusal load was distributed to
adjacent natural teeth to decrease occlusal loads in implants. Our study team previously reported that
10.2% of patients with molar implants showed traumatic occlusion of adjacent premolar teeth, in
which symptoms of traumatic occlusion, such as fremitus, PDL space widening, and tooth mobility,
were observed. They suggested that these results might be due to the lack of PDL and reduced
proprioception around the implants.

The present study found signs of traumatic occlusion, including tooth mobility, fracture, and implant
complications. Mobility of the adjacent tooth was observed in one subject. Occlusal trauma can result in
tooth mobility, but tooth mobility can also result in attachment loss. The patient who showed tooth
mobility in the present study had mild periodontitis; therefore, the effect of attachment loss was
negligible. Three subjects showed fractures of the teeth adjacent to or opposing the canine implants. A
tooth fracture was also observed in our previous study mentioned above. Comparing the present result
with the previous result suggests that teeth adjacent to canine implants seemed to experience more
excessive occlusal forces than teeth adjacent to molar implants. Tooth fractures occurred only in the SP
group. Posterior implants splinted with a canine implant were fabricated to avoid lateral forces exerted
on the implants. As a result, it was speculated that not only would the masticatory discomfort of patients
increase, but unexpected occlusion problems would also arise and excessive forces might be applied to
the anterior teeth during eccentric occlusion or even centric occlusion. As the adjacent teeth in the SP
group were anterior teeth with a single root, occlusal trauma could easily affect them. In the SC group,
most of the canines were congenitally missing, while the other dentition consisted of natural teeth.
Therefore, natural teeth in the posterior area were included in the group function and they might be
adapted to changes in the occlusion scheme. Furthermore, subjects in the SC group were significantly
younger than those in the other two groups, and none had severe periodontitis. Subjects in the SA group
also showed no complications in their adjacent teeth. All adjacent teeth were premolars in this group
because the incisors had been replaced by implants splinted with canine implants. These posterior teeth
might have adapted to changes in the occlusion scheme, as in the SC group.

The complications of adjacent implants include screw loosening, loss of retention, porcelain fracture,
and peri-implant mucositis. The screw loosening and loss of retention occurred in adjacent implants splinted with canine implants. The prevalence of complications from adjacent implants was also compared between the groups. There were no adjacent implants in the SC group; therefore, the difference between the SA and SP groups was evaluated. The prevalence of prosthetic complications did not differ significantly between the SP and SA groups; however, biological complications occurred only in the SP group. However, it is difficult to conclude that these results were obtained only with canine implants. The prevalence of biological complications of implants can be lower in the anterior region than in the posterior region due to the ease of accessibility to maintain oral hygiene in the anterior region.21

The main limitation of this study was that tooth wear was not evaluated because data were retrospectively obtained from chart reviews and panoramic radiographs. Only complications that required additional dental treatment were recorded. Another limitation is the small sample size. Only nine patients were in the SC group because canine teeth were rarely extracted alone.

V. Conclusion

The results of this study suggest that a change in the occlusion scheme from canine guidance to group function due to canine implants can affect adjacent teeth and implants. Canine implants splinted with posterior implants could be more harmful to adjacent teeth than single canine implants or canine implants splinted with anterior implants. However, the prevalence of complications in canine implants and adjacent implants was similar to that in other implants.
